

~~Pitted Keratolysis is a bacterial infection of the foot that causes small pits to form in the skin. The disease is caused by a group of bacteria called Gram-negative bacilli, which are commonly found in the soil and in the water. The bacteria enter the skin through small cuts or abrasions and multiply, causing the skin to become itchy and red. The pits are usually painless and do not cause any long-term damage to the skin. The condition is most common in people who wear shoes for long periods of time, especially in hot and humid climates. The pits are usually found on the soles of the feet, but they can also appear on the sides and between the toes. The condition is usually self-limiting and will resolve itself within a few weeks. However, if the pits do not resolve themselves, it is important to see a doctor for treatment. Treatment usually involves the use of antibiotics and antifungal medications. The pits are usually treated with a topical antibiotic such as clindamycin or erythromycin. In some cases, oral antibiotics may be prescribed. Antifungal medications such as terbinafine or itraconazole may also be used. The pits are usually treated with a combination of antibiotics and antifungal medications. The pits are usually treated with a combination of antibiotics and antifungal medications. The pits are usually treated with a combination of antibiotics and antifungal medications.~~
