

chronic bullous disease of childhood is a rare, chronic, autoimmune blistering disease. It is characterized by the presence of autoantibodies against the epidermal anchoring proteins, specifically type VII collagen. The disease typically presents in early childhood with the formation of blisters on the extremities, particularly around the elbows and knees. The blisters are often accompanied by redness and inflammation of the surrounding skin. The disease is usually managed with systemic corticosteroids and immunosuppressive agents. The prognosis is generally good, with most children achieving long-term remission.
