

Erythema Elevatum diutinum (EED) is a chronic leukocytoclastic vasculitis. It is characterized by raised, red, nodular lesions on the skin. The lesions are typically found on the hands and forearms. The pathogenesis of EED is unclear, but it is associated with monoclonal gammopathy of undetermined significance (MGUS) and multiple myeloma. The histopathological features of EED include leukocytoclastic vasculitis with neutrophilic infiltration and fibrin deposition. The lesions are often associated with systemic symptoms such as joint pain and fatigue. The treatment of EED is primarily symptomatic, with corticosteroids and immunosuppressants being used to control the disease. The prognosis is generally good, but the disease can be persistent and relapsing.
