

Impetigo herpetiformis is a severe form of impetigo, characterized by the presence of large, crusted, and often painful lesions. It is caused by a bacterial infection, typically *Staphylococcus aureus*, and is often associated with underlying conditions such as psoriasis, diabetes, and immunosuppression. The lesions are typically located on the face, neck, and upper extremities, and can be accompanied by systemic symptoms such as fever, malaise, and weight loss. The condition is often misdiagnosed as other skin conditions, such as eczema or contact dermatitis, and requires prompt treatment with antibiotics and supportive care. In severe cases, hospitalization may be necessary to manage the infection and its complications.
