

Amiodarone hyperpigmentation is a common side effect of the drug, which is used to treat various heart conditions. The pigmentation is caused by the accumulation of the drug in the skin, leading to the formation of dark spots and patches. The pigmentation is most commonly seen around the eyes and on the nose, but it can also appear on other parts of the face and body. The pigmentation is usually reversible, but it can take several months or even years to fade away. In some cases, the pigmentation can be treated with topical creams or laser therapy.
