

先天性魚鱗癬 (congenital ichthyosis) is a group of rare genetic disorders characterized by the presence of white, flaky scales on the skin. It is caused by a defect in the gene responsible for the production of keratin, a protein that makes up the outer layer of the skin. The condition is most commonly inherited in an autosomal recessive pattern, meaning that both parents must be carriers of the defective gene for the child to be affected. The severity of the condition can vary, with some children having mild symptoms and others having more severe, life-threatening complications. The condition is often diagnosed in the first few months of life, when the scales are first noticed. Treatment typically involves the use of emollients to keep the skin moist and prevent the scales from becoming too thick. In some cases, more aggressive treatments such as retinoids may be used. The condition is a lifelong condition, but with proper care, children with congenital ichthyosis can lead normal lives.
