Dermatitis Herpetiformis
Dermatitis herpetiformis is an intensely pruritic, chronic recurrent dermatitis that has a slight male predilection. The disease appears with a characteristic papular eruption and an increased but rare risk of lymphoma. Dermatitis herpetiformis in association with SLE has also been reported.
Histopathology
The typical histologic features are best observed in erythematous skin adjacent to early blisters. In these zones, within 1 to 2 days, the rete ridges lose their attachment to the dermis, and the blisters then become unilocular and clinically apparent. At this time, the characteristic papillary microabscesses may be observed at the blister periphery. For this reason, the inclusion of perivesicular skin in the biopsy specimen is of critical importance.

Circulating IgA antibodies that react against reticulin, smooth muscle endomysium, the dietary antigen gluten.

Pathogenesis

Three important findings must be considered in the pathogenesis of dermatitis herpetiformis.
Dermatitis herpetiformis (Duhring's disease) = ديرماتيتيس هيرپتروفيميس (داء دوهرنگ) = ديرماتيتيس عرضات

spruelike changes on jejunal biopsy. Patients with celiac disease develop IgA autoantibodies to tissue transglutaminase.
The IgA deposition results in activation of the complement system followed by chemotaxis of neutrophils.
Ultrastructural Study

The changes in dermatitis herpetiformis resemble those observed in the inflammatory bullae of bullous pemphigoid.
